Short Overview of Some Assays for the Measurement of Antioxidant Activity of Natural Products and Their Relevance in Dermatology

Morana Jaganjac 1, Vesna Sredoja Tisma 2 and Neven Zarkovic 1,*

Abstract: Impaired systemic redox homeostasis is implicated in the onset and development of various diseases, including skin diseases. Therefore, continuous search for natural products with antioxidant bioactivities applicable in biomedicine is attractive topic of general interest. Research efforts aiming to validate antioxidant potentials of natural products has led to the development of several assays based on various test principles. Hence, understanding the advantages and limitations of various assays is important for selection of assays useful to study antioxidant and related bioactivities of natural products of biomedical interest. This review paper gives a short overview on some chemical and cellular bioassays used to estimate the antioxidant activity of chosen natural products together with a brief overview on the use of natural products with antioxidant activities as adjuvant medicinal remedies in dermatology.

Keywords: oxidative stress; antioxidants; assays; natural products; skin diseases

1. Introduction

Physical, psychological, chemical or environmental stress may provoke biological responses that can induce excessive production of reactive oxygen and nitrogen species (ROS and RNS) [1,2], which are otherwise continuously formed endogenously and contribute to the normal, oxidative energy metabolism of cells. ROS were first perceived as harmful byproducts of aerobic metabolism that may promote the onset and development of different diseases, however, their importance in redox signaling and normal cellular functioning is well recognized today. Under normal conditions generation and removal of ROS are in a fine balance. Antioxidant defense systems balance the level of prooxidants and antioxidants to maintain redox homeostasis. Disrupted redox equilibrium in favor of prooxidants will lead to oxidative/nitrosative stress. Depending on the concentration, reactivity and diffusion distance [3], ROS can react with surrounding molecules via different mechanisms, such as hydrogen abstraction and donation or acceptance of electrons [4]. The interaction of ROS/RNS with macromolecules, like proteins, carbohydrates, lipids and nucleic acids, can result in the loss or gain of function, or in the case of lipids can trigger a chain reaction of lipid peroxidation [5–7]. Peroxidation of lipids is of particular biological relevance as it can alter membrane fluidity, transmembrane transport and interaction of macromolecules (i.e., lipid–lipid and lipid–protein) thus impairing normal cell function or even leading to cell death [8]. Among the final products of lipid peroxidation are reactive aldehydes, such as 4-hydroxynonenal (4-HNE), which can, depending on the concentration, have a role either in the physiology or pathology of the cell [9]. In addition, reactive aldehydes are involved in various cellular processes such as regulation of cell growth, inflammation, signal transduction and apoptosis [10–14]. Eventually, 4-HNE can persist in the form of protein...
adducts being able to induce and/or propagate oxidative stress even in the absence of ROS [6,9]. Therefore, it is crucial to maintain cellular antioxidant defenses in order to avoid a rise in 4-HNE concentration from physiological to pathological levels, especially for the cells exposed to potentially harmful effects of chemical (pro-oxidants) or physical inducers (x-rays, UV-irradiation) of ROS/RNS. This is particularly relevant for skin, the largest body organ that serves as biological barrier for physical and chemical environmental factors. These factors may act as oxidants or mediators in the process of generation of ROS and RNS, and together with endogenously formed reactive species make the skin a major target for oxidative stress contributing to the onset and development of various skin pathologies. In addition, skin inflammation is associated with a number of cutaneous diseases. The formation of peroxynitrite (ONOO−), in the reaction between superoxide and nitric oxide (NO•), induces the level of nitrated proteins in the skin contributing to inflammation [15]. Furthermore, ONOO− can induce lipid peroxidation yielding nitrogen-containing oxidized lipid derivatives [16] and may also induce DNA strand breakage further contributing to pathophysiology of inflammation [17].

Natural products with antioxidant bioactivity have long been recognized as a valuable tool in the management of oxidative/nitrosative stress-induced pathologies. This review discusses the natural product discovery workflow to identify products with antioxidant activity, with a focus on available chemical and cellular bioassays used to estimate the antioxidant activity. Finally, at the end of this review, special attention is given to dysregulated redox homeostasis in cutaneous diseases with a brief overview of the potential use of natural products with antioxidant activity as an adjuvant therapeutic approach in dermatology.

2. Synthetic Antioxidants vs. Natural Antioxidants

Substances that can delay or inhibit oxidation of a substrate, or that can upregulate antioxidant defense systems are defined as antioxidants [18,19]. Antioxidant defense systems found in humans are divided into two types: enzymatic antioxidants and non-enzymatic antioxidants. Enzymatic antioxidants are almost exclusively endogenously formed, while the origin of non-enzymatic antioxidants can be either endogenous or exogenous. The nuclear factor erythroid 2-like 2 (Nrf2), thioredoxin and glutathione (GSH) systems are among the major endogenous antioxidant defenses and their mechanisms of action for cellular ROS detoxification have been recently reviewed [20]. Exogenous antioxidants may be of natural or synthetic origin. Synthetic phenolic antioxidants (SPA) are the most frequently used synthetic antioxidants due to their low cost, higher stability and availability. Butylated hydroxytoluene, butylated hydroxyanisole and tert-butyl hydroquinone are among the most frequently used SPAs. SPAs are increasingly used globally in the food industry and consumer products and are unintended contaminants of the environment [21–24]. The emerging evidence stresses that long-term exposure to SPAs has adverse effects on human health [24], and the use of some common SPAs in the European Union has been restricted by several directives. Hence, there is a need to replace them with antioxidants of natural origin. Plants are good sources of natural antioxidants that can in general be classified as phenolic compounds, vitamins and carotenoids [25]. However, although many naturally derived compounds have antioxidant properties, the majority are not suitable for human use. Among the properties to consider are stability, active concentration and safety, just as with medicines and nutraceuticals. Thus, the evaluation of toxicity in the in vitro cellular models should be part of the natural products discovery workflow (Figure 1).
Figure 1. Workflow for the natural products discovery. Extracts from a natural source, such as a plant, may be prepared by either solvent extraction or solvent-free extraction. Solvent extraction is the conventional technique and the polarity index of solvents used will determine the composition of crude extracts [26]. Crude extracts are then examined for potential antioxidant properties by chemical antioxidant and only those identified as bioactive ‘hit’ extracts are further evaluated in the cellular antioxidant assays. Cellular assays also include a toxicity assay to evaluate safety. Extracts acknowledged for their potential antioxidant activity are fractionated based on specific properties in order to reduce the complexity of the extract and preferably isolate pure compounds. High throughput screening (HTS) of each fraction for the antioxidant activity is followed by the purification of compounds from fractions with promising antioxidant activity, structural elucidation and compound identification.

Indeed, before antioxidants can be used as food additives and/or adjuvant medicinal remedies for the integrative biomedicine purposes or as ordinary pharmacological therapeutics, their safety should be assessed by different toxicity tests as requested by the regulatory bodies, such as the European Food Safety Authority and US Food and Drug Administration [25]. Moreover, reactivity and stoichiometric factor, liposolubility and secondary reactions of new natural products with antioxidant activity should be evaluated as well [27].

3. Assays for the Measurement of Antioxidant Activity

Traditionally antioxidant assays are divided into hydrogen atom transfer (HAT), or single electron transfer (SET) based methods (Figure 2) [28]. Although the final products of both mechanisms might be identical, their kinetics greatly differ.

Figure 2. Quenching mechanisms of target radicals by hydrogen atom transfer and/or single electron transfer. AH—antioxidant; A •—antioxidant radical; Phe-O •—aryloxy radical; Phe-OH—phenolic compound; ROO •—target radical.
HAT assays are based on the transfer of hydrogen atoms from antioxidant or phenolic compounds to target radicals, and the kinetics of reaction depends on the solvent used. The hydrogen donation is enhanced in aqueous solutions compared to alcohol ones [29]. However, HAT assays are not dependent on pH, while pH is important for SET assays as an increase in the pH will accelerate electron transfer [30]. Some of the popular HAT-based antioxidant assays are oxygen radical absorbance capacity (ORAC), total radical-trapping antioxidant parameter (TRAP) and β-carotene bleaching assay, while commonly used SET assays include total phenolic assay, 2,3-diphenyl-1-picrylhydrazyl (DPPH) free radical method, trolox equivalent antioxidant capacity (TEAC) and ferric reducing-antioxidant power (FRAP) assay.

3.1. Chemical-Based Antioxidant Assays

Low cost and high-throughput screening (HTS) assays are chemical-based methods preferred for the initial screening process of the natural products discovery workflow. Antioxidants may have different mechanisms of action, according to which antioxidant assays are divided into either (1) scavenging activity assays, (2) reducing antioxidant power assays, (3) lipid peroxidation inhibitory potential or (4) Metal ion chelation (Figure 3).

![Figure 3. Antioxidant chemical-based assays divided based on the antioxidant activity to reducing power, lipid peroxidation inhibition, metal ion chelation and scavenging activity assay. Abbreviations: ABTS—2,2-azinobis-(3-ethylbenzothiazoline-6-sulphonic acid); CERAC—cerium reducing antioxidant capacity; CUPRAC—cupric ion reducing antioxidant capacity; DMPD—N,N-dimethyl-p-phenylene-diamine; DPPH—2,3-diphenyl-1-picrylhydrazyl; FOX—ferrous oxidation-xylenol orange; FTC—ferric thiocyanate; FRAP—ferric reducing-antioxidant power; LDL—low density lipoprotein; LIPIC—lipid peroxidation inhibition capacity; ORAC—oxygen radical absorbance capacity; TEAC—trolox equivalent antioxidant capacity; TRAP—total radical-trapping antioxidant parameter; TBARS—thiobarbituric acid reactive substances.](image.png)

- Scavenging activity assays are based on the ability of an antioxidant to scavenge stable free radicals. Some of the most common antioxidant assays based on scavenging activity include ORAC, DPPH, 2,2′-azinobis-(3-ethylbenzothiazole-6-sulphonate) (ABTS)/TEAC assay and N,N-dimethyl-p-phenylenediamine radical scavenging (DMPD) assay [31,32]. Although the basic principle is the same, their antioxidant solubility differs from those soluble in aqueous and alcoholic media (e.g., ABTS•- and
DMPD•+ radical) to those soluble in organic solvents (e.g., DPPH• radical). Other scavenging assays include those specific to certain ROS/RNS, such as ONOO− [33], hydroxyl radical [34], superoxide anion (O2•−) [35] or NO• scavenging assays [36].

- Reducing antioxidant power assays are based on the principle that antioxidants act as reductants by accepting electrons, for example, from transition metals, notably iron and copper. The most frequently used reducing antioxidant power assays are FRAP, cupric ions reducing power assay (CUPRAC) and total phenolic content assay (Folin–Ciocalteu method) [32].

- The antioxidant assays widely used to evaluate antioxidant ability to inhibit lipid peroxidation include β-carotene bleaching assay, thiobarbituric acid reactive species assay (TBARS), lipid peroxidation inhibition capacity assay (LIPIC) and conjugated dienes [37,38].

- Metal ion chelation is an important property of an antioxidant as transition metals, via the Fenton reaction, promote oxidative stress and lipid peroxidation [2, 39, 40]. Ferrous ion is commonly used to assess the metal chelation capacity of antioxidants [41]. Curcumin, resveratrol, L-carnitine and ferrozine are among many well documented antioxidants with metal chelation ability [32].

Several comprehensive reviews on the strengths and limitations of the above chemical antioxidant assays including the detailed mechanisms behind each assay have been recently published [32,37,41–43].

3.2. Cellular-Based Antioxidant Assays

Natural products identified with potential antioxidant activity need to be further evaluated in the cellular model. Antioxidant activity of a large number of natural products will not extrapolate its performance in the biological system, either in vitro as cellular assays or in vivo as animal model studies. Thus, it is necessary to examine the bioavailability, metabolism and mechanism of action in a living system to prove potential antioxidant activities of new natural products [27]. Although in vivo studies would best reflect the effectiveness of the natural products with antioxidant activity, they are not preferred due to low throughput, occasionally bioethical uncertainties, very high costs and are time-consuming. On the other hand, in vitro cellular models, have high throughput, lower cost and are much faster. Nowadays, a plethora of redox-sensitive probes is available that enable live-cell monitoring of oxidative/nitrosative stress (Figure 4). According to the mechanism of antioxidant activity, cellular antioxidant assays could be divided into those screening for: 1. Direct reaction of antioxidants with ROS/RNS, 2. Organelle/membrane-specific antioxidant activity, 3. Inhibition of oxidant enzymes, and 4. Activators of transcription factors promoting antioxidant defense.

A variety of technologies have been developed to detect ROS/RNS, the selection of which to use will depend on several criteria, such as availability, applicability, specificity, selectivity, throughput and cost. Probes for detection of ROS/RNS in living cells are utilized to evaluate the direct effect of antioxidants on the level of reactive species. Decrease in the level of ROS/RNS can be either due to antioxidants scavenging of reactive species or due to inhibition of their generation. The majority of available probes lack specificity but can provide a good indication of potential antioxidant activity. Such probes are 2′,7′-dichlorodihydrofluorescein diacetate (H2DCFDA), dihydrorhodamine 123 (DHR) and chemiluminescent probes. Although initially H2DCFDA and DHR were perceived to detect hydrogen peroxide and ONOO−, respectively, it was later found that other ROS/RNS, as well as some other cellular molecules, can promote oxidation of the probes giving false-positive results [44]. Chemiluminescent assays, such as luminol or lucigenin-enhanced chemiluminescence have higher sensitivity but are susceptible to redox cycling inducing ROS formation and can, in long-term measurements, give a false increase in the signal. A number of sensitive and selective fluorescent probes for live cells/tissue detection and imaging of ONOO−, such as boronate-based polymeric fluorescent [45], N-phenylrhodol-based HKGreen-4 [46] and rhodamine based HKYellow probes [47] have been developed.
and could be utilized to monitor the effect of antioxidants on ONOO\(^{-}\). Dihydroethidium is another readily used probe that can react with \(\text{O}_2^{••}\) yielding 2-hydroxyethidium that emits red fluorescence (2-OH-E\(^{+}\)). Unfortunately, DHE also nonspecifically reacts with other ROS forming ethidium, a fluorescent product whose spectra overlaps with the spectra of 2-OH-E\(^{+}\) [48]. Thus, when selecting those probes, it is crucial to be aware of all factors affecting the signal and to take precautions to reduce false-positive results.

**Figure 4.** Probes used in HTS assays for the detection of ROS/RNS and lipid peroxidation. Abbreviations: 2-OH-E —2-hydroxyethidium; AO —antioxidants; DCF —dichlorofluorescin; DHE —dihydroethidium; DHR —dihydrorhodamine 123; Et —ethidium; F —fluorescent; H\(_2\)DCFDA —2′,7’-dichlorodihydrofluorescein diacetate; R\(^{+}\) —rhodamine 123.

Spin traps and spin probes used for electron-spin resonance assays have high selectivity and specificity and are among the essential tools in oxidative stress research. Similarly, redox proteomics is rapidly emerging in oxidative stress research as it can identify ROS targets and modifications induced [49–51]. However, low throughput and expensive instruments requiring a high level of expertise reduce their applicability. Hence, these analytical approaches could hardly be the preferred choice for HTS of new natural products.

Organelle/membrane targeted redox sensitive probes allow selection of those antioxidants with organelle/membrane specific effects. The addition of a triphenylphosphonium group to DHE led to the novel probe mitoSOX, that has specificity and selectivity for mitochondria derived \(\text{O}_2^{••}\) [52,53]. Afterwards, numerous organelle-targeting redox sensitive fluorescent probes were developed and validated including the redox-sensitive probes based on the chimeric fluorescent protein [54].

Screening for the antioxidant ability to protect cells from lipid peroxidation should preferably be monitored by the radiometric probe, such is C11-BODIPY\(^{581/591}\). The C11-BODIPY\(^{581/591}\) is a fatty acid analog that emits bright red fluorescence in the intact form. The probe is sensitive to ROS and when oxidized the fluorescence shifts to green [55,56].

Moreover, natural products might not act as scavengers of reactive species, but instead might inhibit activity of pro-oxidant enzymes. Among the pro-oxidant enzymes are NADPH oxidases (NOXs) and their excessive ROS production is implicated in various pathologies. A number of compounds, such as polyphenols and alkaloids from natural sources, were found to decrease or to inhibit NOX activity [57].

In addition, antioxidants could exhibit indirect activity via transcriptional regulation of Nrf2. Nrf2 is the primary redox sensor and the key regulator of endogenous antioxidant
defenses, such as members of the glutathione and thioredoxin systems and superoxide dismutase (SOD) [20].

Based on all the above, two or more cellular-based antioxidant assays should be performed and interpreted in the context of data obtained from both assays to confirm the antioxidant activity of natural products.

4. Natural Products with Antioxidant Activity as Adjuvant Therapeutic Approach in Dermatology

Skin diseases are multifactorial, and oxidative stress plays an important role in the pathophysiology of many autoimmune and inflammatory diseases, as well as in other stress- and age-dependent diseases. Accumulating evidence shows that impaired antioxidant defenses [39,40,58–60] and increased levels of oxidants [39,59–64] are important mediators in the pathology of a plethora of cutaneous diseases (Table 1).

The SOD enzyme that accelerates the conversion of the $\ce{O2^-}$ to hydrogen peroxide ($\ce{H2O2}$), is decreased in psoriasis [65], alopecia areata [58], acne vulgaris [61], systemic sclerosis [62] and seborrhoeic dermatitis [59]. Alterations in the glutathione system, one of the major endogenous antioxidant defenses, were reported for alopecia areata [58], psoriasis [65], oral lichen planus [70] and atopic dermatitis [73]. In addition, vitiligo is also accompanied by decreased antioxidant defenses [67] and elevated oxidation products [68,69] that mediate the death of melanocytes [74]. Deregulated redox homeostasis and oxidation of macromolecules further accompany cutaneous disease pathology [40,61,68,71]. Nowadays, antioxidants from plants with potential antioxidant activity are emerging as potential adjuvant therapies for cutaneous diseases in order to prevent the development of various symptoms. In the Table 2 we provide a list of some natural products with antioxidant activity and with traditional, ethnomedical applications as adjuvant treatments for cutaneous diseases, or those experimentally shown in a disease model to have beneficial effects.

It is obvious that numerous plant extracts possess the capacity for medicinal applications aiming at attenuating symptoms of skin diseases, preventing their occurrence and even to be used for adjuvant therapeutic remedies or nutraceuticals. However, must follow strict regulatory rules and should be proven for their efficiency as antioxidants before being used as such.

5. Conclusions and Future Perspectives

While stress- and age-associated disorders are usually considered to affect internal organs, they very often manifest as skin diseases, mostly associated with skin exposure to UV light, environmental pollutants, persistent oxidative stress and chronic inflammatory processes. However, even local manifestations of the many diseases are often associated with systemic disorders of oxidative homeostasis. Therefore, if intended to be used as adjuvant medicinal remedies or even cosmetics, natural products with antioxidant potential are obliged to meet the high safety and efficacy standards, as do other medicinal remedies. They should be tested for their bioactivities using complementary assays for antioxidants. Whenever possible, antioxidant effects should be complemented by analysis of the potential pro-oxidant effects of the chosen substance(s) in the presence of biofluids (preferably serum), thus resembling complex in vivo processes, as do enzymatic assays for antioxidant capacity and peroxides [121]. Complementary to that, options for in vitro bioassays should be developed to reveal at the same time pro- and anti-oxidant activities thus resembling living systems as in the case of the 4-HNE-Cell ELISA assay, which was recently used to prove cell-type specific bioactivities of the *Aloe vera* extracts [122].

**Author Contributions:** Conceptualization, M.J. and N.Z.; investigation, M.J. and V.S.T.; writing—original draft preparation, M.J., V.S.T. and N.Z.; writing—review and editing, M.J. and N.Z.; visualization, M.J. and V.S.T. All authors have read and agreed to the published version of the manuscript.

**Funding:** This research received no external funding.

**Conflicts of Interest:** The authors declare no conflict of interest.
